Key words: Dam, Spillway, Scour, Pressure fluctuations, Erodibility index, CFD.

Summary. The study analyzes the expected changes in the Paute River, located in Ecuador, as a result of the construction of the Paute-Cardenillo Dam (owned by Celec Ep-Hidropaute). The dam will integrate the National Electric System of Ecuador with a total electricity installed capacity of 600 MW which will produce 13000 GWh per year. To evaluate the stability and safety of the structure, it is necessary to ascertain the shape and dimensions of the scour generated downstream from the dam. The scour, due to the operation of the spillway and outlets, is studied with three complementary procedures: empirical formulae obtained in models and prototypes, semi-empirical methodology based on pressure fluctuations-erodibility index and computational fluid dynamics simulations.

1 DAM CHARACTERISTICS

The Paute-Cardenillo Dam, located in Ecuador, is a double curvature arch dam with a maximum height of 135 m to the foundations. The top level is located at 926 meters above mean sea level (MASL). The reservoir has a length of 2.98 km with normal maximum water level located at 924 MASL. The river bed consists of a layer of 24 m of alluvial, below which there is a layer of 10 m of weathered rock. It has a free surface weir controlled by sluices that spill a flow of \(Q_4 = 700 \text{ m}^3/\text{s}\) (return period \(TR = 4 \text{ years}\)) and a half-height outlet with two almost symmetrical ducts. Considering the maximum normal operating level (924 MASL), the intermediate outlet capacity is \(Q_{40} = 1760 \text{ m}^3/\text{s}\). Hence, the total flow of the weir and half-height outlet is \(Q_{100} = 2340 \text{ m}^3/\text{s}\). If the bottom outlet were considered, the discharge capacity of the dam would be \(Q_{10000} = 5520 \text{ m}^3/\text{s}\).

2 EMPIRICAL FORMULAE

In the study, 29 formulae are examined. The scour hole is estimated for different return periods flows.

Most of the equations were obtained by dimensional and statistic analysis of data obtained in Froude scale reduced models, with few formulae based on prototypes and many obtained for the ski-jump. As discharge is produced by a free surface weir and in pressure conditions by an intermediate outlet, the general expression is modified which provides the following
simplified general expression:

$$D_s = h + D = K \frac{q^x h^y H^w}{g^z}$$

where $D_s$ is the scour depth below tailwater level, $h$ the tailwater depth, $D$ the scour depth below the original bed, $K$ an experimental coefficient, $q$ the specific flow, $H_n$ the energy net head, and $d$ the characteristic size of bed material. The meaning of the rest variables can be seen in Figure 1.

**Figure 1:** Scheme of scour in Paute-Cardenillo Dam

Table 1 shows the coefficients corresponding to five simplified formulae with values that fall in the mean values +/- 1 standard deviation, while Table 2 shows five more general expressions with values in the same range.

Figure 2 shows the results obtained for the free surface weir. The mean value +/- 1 standard deviation is indicated. If the mean value for the design flow (700 m$^3$/s) were considered, the scour could reach a depth of 15 m. However, if the mean value + 1 standard deviation were taken into account, then the flow of 500 m$^3$/s would penetrate the weathered rock (scour about 30 m).

Table 2: Five scour general formulae with values that fall in the mean value +/- 1 standard deviation

\[
D_s = 0.640^0.5H^{0.25}(h/d_m)^{0.333}
\]

\[
D_s = h + 0.19\left(\frac{H + h}{d_{90}}\right)^{0.75}\left(\frac{H^{0.47}h^{0.33}}{K}\right)
\]

\[
D_s = \left(\frac{0.97}{\sqrt{d_m}} - \frac{1.35}{\sqrt{H}}\right) + q \cdot \sin \theta r \cdot \cos \theta r + 0.25h
\]

\[
D_s = 3.39q^{0.60}(1 + \beta)^{0.30}h^{0.16}
\]

\[
D_s = K^{0.67}H^{0.67}h^{0.33}\left(\frac{\rho}{\rho_s}\right)
\]

\(d_{av}\). Average particle size of the bed material.  
\(d_{90}\). Bed material size in which 90% is smaller in weight.  
\(\theta r\). Impingement jet angle.  
\(g\) (9.81 m/s²). Gravity.  
\(\beta\). Air-water relationship.  
\(\rho\). Water density.  
\(\rho_s\). Density of sediment.

Figure 2: Scour of alluvial and weathered rock for the free surface weir
Figure 3 shows the results obtained for the half-height outlet. The mean value +/- 1 standard deviation is indicated. The jet would scour the alluvial layer (24 m) with a return period flow $Q_{22} = 1320$ m$^3$/s. The design flow ($Q_{40} = 1760$ m$^3$/s) would not reach the intact rock. However, if the mean value + 1 standard deviation were taken into account, then the flow of 1250 m$^3$/s would erode the weathered rock layer (scour about 34 m).

3 SEMI-EMPIRICAL METHODOLOGY

The erodibility index is based on an erosive threshold that relates the magnitude of relative erosion capacity of water and the relative capacity of a material (natural or artificial) to resisting scour. There is a correlation between the stream power or magnitude of the erosive capacity of water ($P$) and a mathematical function $[f(K)]$ that represents the relative capacity of the material to resisting erosion. On the erosion threshold, this may be expressed by the relationship $P = f(K)$. If $P > f(K)$, the erosion threshold is being exceeded and the material is eroded.

Scour in turbulent flow is not a shear process. It is caused by turbulent, fluctuating pressures (Annandale [2]). Quantification of pressure fluctuations of incident jets in stilling basins has been studied mainly by Ervine and Falvey [20], Ervine et al. [21], Castillo [9, 11, 12, 14], Castillo et al. [10, 13], Puertas [35], Bollaert [4], Bollaert and Schleiss [5], Melo et al. [33], Felderspiel [22], and Carrillo [8].

The dynamic pressures of jets are a function of the turbulence intensity at the discharge conditions, length of the jet flight, diameter (circular jet) or thickness (rectangular jet) in impingement jet conditions and water cushion depth. Annandale [1, 2] summarized and established a relationship between the stream power and the erodibility index for a wide range of discharge conditions.
variety of materials and flow conditions. The stream power per unit of area available of an impingement jet is:

\[ P_{Jet} = \frac{\gamma Q H}{A} \]  

(2)

where \( \gamma \) is the specific weight of water, \( Q \) the flow, \( H \) the drop height or the upstream energy head, and \( A \) the jet area on the impact surface. The erodibility index is defined as:

\[ K = M_s \cdot K_b \cdot K_d \cdot J_s \]  

(3)

where \( M_s \) is the number of resistance of the mass, \( K_b \) the number of the block size, \( K_d \) the number of resistance to shear strength on the discontinuity contour, and \( J_s \) the number of structure relative of the grain. Table 3 shows the formulae of the parameters.

</tr>
</tbody>
</table>

The threshold of rock strength to the stream power, expressed in kW/m\(^2\), is calculated and based on the erodibility index \( K \):

\[ P_{rock} = 0.48K^{0.44} \]  

if \( K \leq 0.1 \)

\[ P_{rock} = K^{0.75} \]  

if \( K > 0.1 \)

The dynamic pressure in the bottom of the stilling basin is based on two components: the mean dynamic pressure (\( C_p \)) and the fluctuating dynamic pressure (\( C_p^{'} \)). These dynamic pressure coefficients are used as estimators of the stream power reduction coefficients, by an effect of the jet disintegration in the air and their diffusion in the stilling basin.
Hence, the dynamic pressures are also a function of the fall height to disintegration height ratio \((H/L_b)\) and water cushion to impingement jet thickness \((Y/B_j)\). Thus, the total dynamic pressure is expressed as:

\[
P_{\text{total}} = C_p(Y/B_j)P_{\text{jet}} + FC_p'(Y/B_j)P_{\text{jet}}
\]  

(5)

where \(C_p(Y/B_j)\) is the mean dynamic pressure coefficient, \(C_p'(Y/B_j)\) the fluctuating dynamic pressure coefficient, \(P_{\text{jet}}\) the stream power per unit of area, and \(F\) the reduction factor of the fluctuating dynamic pressure coefficient. In rectangular jet case (nappe flow), Castillo and Carrillo [16] and Carrillo [8] adjusted the formulae by using new laboratory data (Figures 4, 5 and 6).

Considering a water cushion depth of 24 m, the flow rate of 500 m$^3$/s would have the power to erode weathered rock, although the design flow of 700 m$^3$/s would not have enough power to erode the intact rock. These results confirm that the maximum scour of the free surface weir could be near to 34 m.

We can observe that the half-height outlet case does not correspond strictly with circular neither rectangular (nappe flow) jet case. For circular jets, the $C_p$ and $C_p'$ are valid for $H/L_b \leq 0.50$ (Ervine et al., [21]). However, for the design flow ($Q_{d0} = 1760$ m$^3$/s) the $H/L_b = 1.67$. For this reason the calculus were carried out by using the rectangular analogy.

The stream power threshold of weathered rock ($P_{\text{weathered rock}} = 16$ kW/m$^2$) does not resist the flow of annual return period ($Q_{ma} = 136$ m$^3$/s). The intact rock stream power ($P_{\text{rock}} = 408$ kW/m$^2$) could resist up to a flow return period of 5 years ($Q_5 = 820$ m$^3$/s). The $Q_{10} = 1180$ m$^3$/s would exceed the rock strength.

As a solution to the scour, a concrete slab of 20 MPa characteristic strength and thickness of 2 m ($P_{\text{conc}} = 788$ kW/m$^2$) is placed directly on the alluvial level (796 MASL). The geometry of the pre-excavated basin should be similar to the geometry of the basin that would be formed with the flow $Q_{d0} = 1760$ m$^3$/s. Figure 8 indicates that the concrete slab would resist the power stream of the design flow ($P_{\text{jet}} = 664.95$ kW/m$^2$).

4 NUMERICAL SIMULATION

As a complement of the empirical and semi-empirical methodologies, three-dimensional mathematical model simulations were carried out. These programs allow a more detailed characterization than one-dimensional and two-dimensional numerical models and, thus, a detailed study of local effects of the sediments transport. The numerical simulation of the hydraulic behavior and scour by the action of the free surface weir, intermediate and bottom outlets were also analyzed.

The computational fluid dynamics (CFD) program FLOW-3D was used. This program solves the Navier-Stokes equations discretized by finite differences. It incorporates various turbulence models, a sediment transport model and an empirical model bed erosion (Guo [24]; Mastbergen and Von den Berg [32]; Brethour and Burnham [7]), together with a method for calculating the free surface of the fluid without solving the air component (Hirt and Nichols [26]). Pressures obtained in the stagnation point and their associated mean dynamic pressure coefficients were compared with the parametric methodology proposed by Castillo [12, 14], actualized by Castillo and Carrillo [16] and Carrillo [8].

In order to simulate the proper functioning of the free surface weir, several simulations were carried out by means of sensibility analysis: air entrainment models, turbulence models, grid size and type of solver, among others (Figure 9).
We can observe that the results are anomalous when RNG $k$-$\varepsilon$ turbulence model and the one fluid free surface method are used. So, if the mesh size is reduced from 0.30 m to 0.20 m, $C_p$ changes from 0.71 to 0.90. However, when the RNG $k$-$\varepsilon$ model is used with the split Lagrangian free surface method, then the results are more similar to the expected value.

The most accurate results were obtained by using a mesh size of 0.2 m, and large eddy simulation (LES) turbulence model. In the solver options, the stability and convergence method was selected and the free surface solved with the split Lagrangian method.

Table 6 compares the mean pressure and the mean dynamic pressure coefficient obtained by the non-effective water cushion case. Results were similar to the parametric methodology. It may be observed that the mean dynamic pressure and $C_p$ coefficient obtained with FLOW-3D are somewhat greater than parametric methodology values, which is due to the air entrainment model not resolving the two-phase flow in an appropriate way.

**Table 6**: Comparison of pressures and $C_p$, considering a water cushion depth of 2 m

</tbody>
</table>
As far as scour is concerned, free surface weir jets tended to impact on a small area. The upstream face of the scour bowl occurred approximately 29 m downstream from the dam. The plant scour was near 24 m long and 53 m wide (Figure 10). Erosion generated a scour depth of 22 m, which was a little greater than that calculated with the mean value of the empirical formulae and similar to that obtained with semi-empirical methodology.

![Figure 10: Front, lateral, and top view of the scour due to the free surface weir](image)

For the simulation of half-height outlet ducts (5.00 x 5.80 m), the selection of the mesh size is function of their dimensions and of the thickness of the falling jets. The mesh consisted in hexahedral elements of 1 m. The Re-Normalization Group (RNG) $k-\varepsilon$ turbulence model was selected. The volume-of-fluid advection was solved with the Split Lagrangian method. The time-step size was controlled by stability and convergence criteria.

Pressures obtained in the stagnation point and their associated mean dynamic pressure coefficients were compared with the parametric methodology [12, 14, 16, 8].

As far as the numerical simulation is concerned, the scour shape considering the concrete slab was analyzed. In this way, the level 798 m was considered as a non erodible. For the design flow, the half-height outlet jets tend to impact on a small area.

The upstream face of the scour occurred approximately 85 m downstream from the dam. The plant scour was near 108 m long and 50 m wide (Figure 11). Scour would reach the left natural slope and could cause landslides. The pre-excavated stilling basin shape should be adjusted to the geometry and the space available. Figure 12 shows the velocities vectors in lateral and top views of the pre-excavated basin.
Figure 11: Top, front and lateral views of the scour due to the half-height outlet

Figure 12: Lateral and top views of the velocity vectors in the pre-excavated stilling basin

5 CONCLUSION

In this paper, similar results have been obtained by solving the problem from three different perspectives: empirical formulations, erosion potential semi-empirical formulation and CFD simulations.

The results demonstrate the suitability of crossing methodologies to solve complex phenomena. Thus, numerical simulations were used to complement the classical formulations, allowing a better understanding of the physical phenomena in order to obtain an adequate solution. Methodology leads us to propose a pre-excavated stilling basin.
The basin would allow to generate an effective water cushion. Besides this, it would reduce the sedimentation due to the excavation and the material transported by the river, especially during the flushing operations of the reservoir. The pre-excavated basin also would help to have a symmetric and regular flow, reducing the risk of potential landslides.
